

Who gives? A literature review of predictors of charitable giving

Part One: Religion, education, age and socialisation

René Bekkers and Pamala Wiepking

This is the first of two papers in which we present a comprehensive review of the multidisciplinary academic literature on philanthropy, identifying the predictors of charitable giving by individuals and households. For each predictor, we discuss the evidence for the mechanisms that may explain why the predictor is correlated with giving. We conclude with a brief agenda for future research. In this first paper we present the evidence on the relationship of giving with religion, education, age and socialisation.

Introduction

The academic literature on charitable giving is enormous. On Google Scholar, the keyword ‘charitable giving’ yields more than 163,000 results. Moreover, the literature is spread over many different disciplines, including economics, sociology and (social) psychology. As a result, it is difficult for scholars and practitioners to get an overview of the literature. The present paper is the second journal paper resulting from a comprehensive project reviewing the literature on charitable giving by individuals and households (Bekkers and Wiepking, 2007) that we conducted as a background study for the Science of Generosity at the University of Notre Dame, a funding scheme sponsored by the John Templeton Foundation. In line with most of the literature, we define charitable giving as the voluntary donation of money to an organisation benefiting others beyond one’s own family.

In the first paper (Bekkers and Wiepking, 2010b) we categorised and described the eight major mechanisms that drive charitable giving, addressing the question: ‘Why do people give?’ The mechanisms are:

- awareness of need;
- solicitation;
- costs and benefits;
- altruism;
- reputation;
- psychological benefits;
- values;
- efficacy.

In the present and following second paper, which will appear in a future issue of *Voluntary Sector Review*, we aim to guide scholars as well as practitioners in the third

Key words charitable giving · philanthropy · donations · literature review

sector through the available knowledge on individual and household characteristics as predictors of charitable giving. We address the question: 'Who gives?'. In this first paper, we present the evidence on religion, age, education and socialisation practices as correlates of charitable giving. In the second paper we discuss the evidence on gender, marital status, income and wealth. For the sake of brevity we omit discussion of variables that have been studied less frequently, such as voluntary association participation, occupational prestige, political preference and health, instead referring the reader to the original literature review.

Why would it be important to know who gives to charitable causes? Obviously, the answer is of great practical importance for organisations that rely on fundraising to generate income. Charitable donations form a substantial portion of income for many non-profit organisations across the world (Anheier and Salamon, 2006). Knowing which characteristics of individuals and households are predictive of donations informs rational decisions on fundraising strategies.

For scholars, charitable giving is a fascinating form of human behaviour because it presents challenges for several theoretical perspectives. Questions about altruism and generosity go back to the founding fathers of economics and sociology, such as Adam Smith (1976 [1759]) and Auguste Comte (1973 [1851]). Empirical research on who gives is useful for testing theories on charitable giving. Stated generally, hypotheses about the relationship between charitable giving and characteristics of individuals and households imply arguments about the relationship between these characteristics and the mechanisms that drive charitable giving.

In a multiple regression framework, the mechanisms that drive charitable giving can be viewed as intermediary variables. They may mediate the relationship between individual or household characteristics and charitable giving, explaining why some people give more than others. We advocate such an approach in research on charitable giving. Many articles present regression analyses of amounts donated on a set of 'standard predictors'. But without explicit arguments about the pathways linking individual and household characteristics to charitable giving, even the most sophisticated econometric analyses remain superficial 'variable sociology' (Esser, 1996; Goldthorpe, 2001). Therefore, we do not merely summarise the evidence on relationships between charitable giving and individual and household characteristics, we also discuss the mechanisms that may explain why these relationships exist.

While we present various mechanisms as mediating variables, we acknowledge the possibility that the mechanisms precede the individual or household characteristics in a multiple regression framework. For instance, values may determine the level of church attendance and altruism plays a role in maintenance of relationships. For matters of simplicity, we do not discuss these relations in this paper and instead focus on the mechanisms as mediators between household or individual characteristics and giving. Nevertheless, we remind the reader that arguments about causality are very difficult if not impossible to substantiate using cross-sectional data.

Methods

The present paper and its twin sister are based on an extensive literature search using fairly narrow criteria through seven types of sources, which eventually yielded a set of about 550 publications. We restricted our review to publications in English of empirical research on charitable giving by adults included in academic databases. We refer to our first paper based on the review (Bekkers and Wiepking, 2010b) for a full description of the sources and criteria used. Quite a few of the papers that were still work in progress when we completed our literature search in August 2007 have subsequently been published in academic journals. Here we refer to the published versions of those papers.

For the purposes of this overview paper, it is not possible to provide extensive and comparative details on the data and methods used in the studies that find results that are consistent with the overall picture emerging from these studies. However, we do discuss data and methodology issues when the findings of a study diverge from those in other studies that examined the same variables.

Throughout the paper, we distinguish engagement in charitable giving (whether or not a donation is made, sometimes called ‘participation’) from the amount donated (sometimes called the ‘level of giving’) when the conclusions for these two different variables diverge. When the conclusions are similar for associations with participation in giving and levels of giving, we simply refer to ‘higher/lower giving’.

Results

The characteristics that emerge from our literature review as typical for donors are:

- affiliation with a religion (especially Judaism and Protestantism);
- stronger religious involvement;
- a higher age;
- a higher level of education;
- income and wealth;
- home ownership;
- a better subjective financial position;
- being married;
- having children;
- having a paid job;
- higher cognitive ability;
- having prosocial personality characteristics such as empathy;
- growing up with parents with higher education, income, religiosity and volunteering activity.

The evidence on town size, gender, race and political preferences is mixed. In this paper we will discuss the relationship of giving with religion, education, age and socialisation.

Religion

Religion’s influence on giving has received ample attention not only in philanthropic studies (Hodgkinson and Weitzman, 1996) but also in the sociology of religion (eg, Wuthnow, 1991; the December 1994 volume of the *Review of Religious Research*)

Under the generic label 'religion', several more specific characteristics should be distinguished, four of which have been studied most frequently:

- religious affiliation or church membership, that is, whether one is a member of a religious group or church;
- religious attendance involvement or participation, that is, to what extent one participates in a religious group;
- religious preference or denomination, that is, to which religious group one belongs;
- religious belief, that is, the content of one's religious views.

Church membership and attendance

Positive relationships between church membership, the frequency of church attendance and giving appear in almost all papers in which this relation has been studied (Sullivan, 1985; Schiff, 1990; Zaleski and Zech, 1992, 1994; Davidson and Pyle, 1994; Hoge and Yang, 1994; Olson and Caddell, 1994; Jackson et al, 1995; Sokolowski, 1996; Forbes and Zampelli, 1997; Schlegelmilch et al, 1997; Regnerus et al, 1998; Hunter et al, 1999; Bennett and Kottasz, 2000; Lunn et al, 2001; Reed and Selbee, 2001, 2002; Tiehen, 2001; Chaves, 2002; Eschholz and Van Slyke, 2002; Bekkers, 2003; Brooks, 2003b, 2003c, 2004; Bryant et al, 2003; Eckel and Grossman, 2003; Lee and Farrell, 2003; Park and Park, 2004; Bielefeld et al, 2005; Chang, 2005; Lyons and Passey, 2005; Van Slyke and Brooks, 2005; Lyons and Nivison-Smith, 2006; Brown and Ferris, 2007; Feldman, 2007; Bekkers and Schuyt, 2008). Church members are more likely to report engagement in charitable giving and report higher donations. More frequent church attendance is also associated with higher levels of engagement in charitable giving and higher amounts donated.

Specific types of giving

The finding that church membership and attendance are associated with more giving is hardly surprising. It may even be called tautological as membership, attendance and giving are all indicators of religious involvement. Therefore, many studies have looked specifically at the relationships between religious involvement and giving to organisations other than the church itself, often referred to as 'secular giving'. The common finding in these studies is that secular giving is also positively associated with religious affiliation and attendance (Bennett and Kottasz, 2000; Brooks, 2003b; Eckel and Grossman, 2003; Bielefeld et al, 2005; Lyons and Nivison-Smith, 2006; Brown and Ferris, 2007; Bekkers and Schuyt, 2008).

However, there are also a few exceptions. One study among Presbyterians in the United States (US) found a negative relationship between religious attendance and secular giving (Lunn et al, 2001). One study using data from the Center on Philanthropy Panel Study (COPPS) found no relationship between religious affiliation and secular giving (Wilhelm et al, 2008). This study applied an extensive

set of controls, including concurrent parental giving, and the results indicate that the relationship between religious affiliation and secular giving might be spurious. Two studies from Australia reported this finding at the high end of the distribution of religious involvement – that is, attending church more than once a week (Lyons and Passey, 2005; Lyons and Nivison-Smith, 2006). Brooks (2004) found no relationship between self-identifying as Christian and secular philanthropy. In a later study the relationship between (more than) weekly church attendance and secular philanthropy was negative (Brooks, 2005), while rarely/never attending church was negatively related to both religious and secular philanthropy. A study of giving to human services found no relationship with religious affiliation (Marx, 2000).

Another exception to the regularity of the finding that religious involvement is positively related to charitable giving comes from several experiments in which the participants had an opportunity to donate in a non-religious context (Eckel and Grossman, 2004; Bekkers, 2006c, 2007). One study, however, did find higher giving by religious participants (Eckel and Grossman, 2003). The fact that no statistically significant relationship between giving and religious involvement was found in three out of four experiments is informative about the mechanisms that mediate the relationship between religious involvement and giving, which we discuss later.

Denomination

Several studies have looked at differences between religious groups or denominations. In these studies, Protestants were often found to give more than Catholics, at least in the US, Canada and the Netherlands (Zaleski and Zech, 1992, 1994; Hoge and Yang, 1994; Forbes and Zampelli, 1997; Reed and Selbee, 2001; Chaves, 2002; Berger, 2006; Bekkers and Schuyt, 2008). Studies that have used more refined categories of religious denominations found that more conservative Protestants gave more than the more liberal groups of Protestants (Berger, 2006; Brooks, 2006; Bekkers and Schuyt, 2008). Only a few studies have considered donations by other religious groups. Hoge and Yang (1994) found that Jews donated higher amounts than Catholics and Protestants, but not as a proportion of income. In Canada, Jews were found to donate amounts similar to Protestants but lower proportions of income (Berger, 2006). In South Africa, Christians were more likely to engage in philanthropy than non-Christians or the non-religious (Everatt et al, 2005).

Religious beliefs

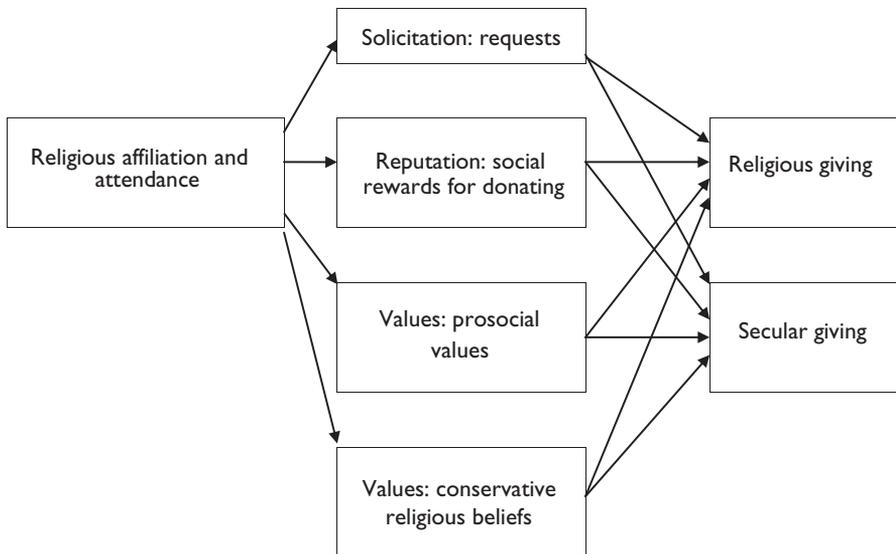

Religious beliefs have only rarely been analysed in relation to philanthropy. Davidson and Pyle (1994) found that more orthodox and stronger religious beliefs were positively related to religious contributions. They also found that this relationship was mediated by church attendance, which indicates that people with more orthodox religious beliefs give more to their church because they are more strongly involved in the religious community. Olson and Caddell (1994) and Bekkers and Schuyt (2008) found that salience of religion (agreement with the statement that religion is important in the respondent's life) was positively related to religious giving mainly

through church attendance. These results are in line with the finding by Davidson and Pyle (1994) because persons with more orthodox beliefs tend to find religion more important in their lives. A study among Presbyterians found that orthodox beliefs were negatively related to denominational contributions and donations to non-religious charities, but positively related to congregational and other giving, controlling for church attendance (Lunn et al, 2001). Similar findings were reported in a national US study (Brooks, 2004).

Mechanisms

Why would there be differences in giving between religious denominations? And why do people who attend religious services more often donate higher amounts? Which mechanisms may explain these differences? In Figure 1 we have displayed the mechanisms that are emerging from the literature as explanations for the effects of religion on philanthropy.²

Figure 1: Mechanisms explaining the relationships between charitable giving and religious affiliation and attendance

Note: All displayed relationships are positive unless noted otherwise

The difference between results from survey research and experiments suggests a potential role for solicitation (the likelihood of being asked to donate), reputation (the social rewards of donating) and values (the ideals people would like to see realised through their donation). The experimental results suggest that the religious are not necessarily more willing to donate than the non-religious when asked to donate to pre-selected secular organisations. One key aspect of experiments is that solicitation is kept constant. All participants, whether religious or not, get the same opportunity

to donate. Beyond these experimentally induced situations, however, religious persons receive more solicitations to contribute to charitable donations than non-religious persons (Bekkers, 2005b; Bekkers and Schuyt, 2008).

Another difference between donating money to charity in the experiments (as conducted thus far) and donating money in ordinary situations is the possibility of obtaining social rewards for donations. In the experiments, donations were made privately, in the absence of others and they were not announced to others. It is well known that anonymity reduces donations (eg, Hoffman et al, 1996; a more comprehensive list of studies is in our paper describing the mechanisms: Bekkers and Wiepking, 2010b). The lack of a relationship between religion and giving in experiments may thus indicate that the higher giving among the religious is due to a heightened sensitivity to reputation among the religious. As one interesting experiment showed, a failure to give has a more negative effect on the reputation of religious persons than on that of non-religious persons (Bailey and Young, 1986).

Consistent with reputation as an explanatory mechanism, Berger (2006) found that Protestants in Canada were giving more than Catholics and the non-religious because of the stronger social norms on giving that they faced along with their higher level of church attendance. This finding is in line with the finding of a US study that 'public profession of faith is more strongly related to religious contributions than private devotional activities' (Davidson and Pyle, 1994: 192). A survey study in the Netherlands found that the higher level of religious giving among Protestants there is due to a higher number of solicitations for contributions and a higher level of social pressure to conform to group standards (Bekkers and Schuyt, 2008). Brown and Ferris (2007) found that, controlling for social capital measures, including membership of organisations and social trust, an initially positive relationship between salience of religion and secular giving was actually reversed, to a significantly negative relationship.

On the other hand, in a study comparing reported donations in a survey on giving with actual donations as registered by a secular Dutch health charity, Bekkers and Wiepking (2010a) found that Protestants under-reported their donations in the survey when compared with their actual registered donations. This indicates that Protestants – at least in the Netherlands – do not like to share information on their donation behaviour with others, as illustrated in the biblical quotation "do not let your left hand know what your right hand is doing" (Matthew 6: 3). Hence, a reputation effect might not account for heightened giving by all religious people in all countries. Bekkers and Wiepking (2010a) explained the under-reporting of the Protestants as a result of altruistic and religious values.

Thus, solicitation and reputation may not be the only two mechanisms involved in the relationship between religion and giving. Values also play a role. Decisions to attend church and to give to church are likely to be determined by a shared set of religious preferences, such as theological beliefs (Sullivan, 1985; Lunn et al, 2001; Bekkers and Schuyt, 2008). The experiments failing to find a relationship between religion and giving gave participants the opportunity to donate to secular organisations. Churches were not included as potential recipient organisations. A preference to donate to churches and religious organisations may explain the lack of a relationship between religion and giving in experiments. At the same time, the religious have stronger

prosocial values – such as social responsibility and altruistic values (Hardy and Carlo, 2005; Bekkers and Schuyt, 2008). One survey study of donations in the Netherlands showed that controlling for prosocial values reduces the relationship between religion and giving – especially to secular causes (Bekkers and Schuyt, 2008).

Finally, differences in psychological benefits are likely to play a role in denominational differences in giving. Several survey studies suggest that differences in solicitation methods may account for differences in level of religious giving between denominations. Protestant congregations more often use tithing and annual pledges, whereas Catholics mainly use the collection basket in church to collect donations (Hoge and Yang, 1994; Zaleski and Zech, 1994; Zaleski et al, 1994). The annual pledge may be viewed as a fundraising application of the promise elicitation technique, creating psychological costs for breaking a promise (Cialdini, 2001).

Education

The level of education is the second ubiquitous correlate of charitable giving. Positive relations between the level of education and giving are found in most empirical studies that have included education as a variable (Yavas et al, 1981; Reece and Zieschang, 1985; Kingma, 1989; Schiff, 1990; Jones and Posnett, 1991a; Brown and Lankford, 1992; McClelland and Kokoski, 1994; Olson and Caddell, 1994; Sokolowski, 1996; Pharoah and Tanner, 1997; Schlegelmilch et al, 1997; Banks and Tanner, 1999; Chua and Wong, 1999; Duncan, 1999; Todd and Lawson, 1999; Rooney et al, 2001; Tiehen, 2001; Eschholz and Van Slyke, 2002; Reed and Selbee, 2002; Bekkers, 2003, 2006b; Brooks, 2003a, 2003b, 2004; Apinunmahakul and Devlin, 2004; Gruber, 2004; Bielefeld et al, 2005; Brown, 2005; Chang, 2005; Lyons and Passey, 2005; Van Slyke and Brooks, 2005; Yamauchi and Yokoyama, 2005; Bekkers and De Graaf, 2006; Carroll et al, 2006; Houston, 2006; Lyons and Nivison-Smith, 2006; Matsunaga, 2006; Mesch et al, 2006; Brown and Ferris, 2007; Feldman, 2007; Wilhelm et al, 2008; Wiepking and Maas, 2009b). Higher levels of education are also associated with giving a higher proportion of income (Schervish and Havens, 1997).

Specific types of giving

While the relationship between education and total annual giving is usually found to be positive, the relationship of education with giving is by no means the same across charitable subsectors. In a study of donations to specific types of charitable organisations in Austria, education was positively related to donations to environment and animal protection, development aid, and human rights but negatively related to donations to healthcare and emergency aid (Srnka et al, 2003). The negative relationship between education and giving to health also emerged from studies of donations to the American Lung Association (Keyt et al, 2002) and the Dutch Heart Association (Bekkers, 2008). In the US, Knoke (1990) found a negative relationship between the level of education and annual donations to 35 professional societies, recreational organisations and women's associations, controlling for income and occupational prestige. In two other studies from the US, education did not correlate

with the likelihood of giving to the poor (Regnerus et al, 1998) and to human services (Marx, 2000). A field experiment with mail solicitations to fund a new centre for environmental policy analysis in the US found no effect of education (List, 2004).

Specific populations

Wu et al (2004) found no effect of education on the likelihood of giving in Taiwan, although the amount donated was positively related to education. Park and Park (2004) found no relationship between education and donations in Korea. Feldstein and Clotfelter (1976) found no difference between college graduates and those with lower education, controlling for wealth, income and tax price. Hoge and Yang (1994) found a positive relationship of education with religious contributions for Protestants, but not for Catholics.

Model specification

Using data on the US from the 1994 Survey of Giving and Volunteering, Bryant et al (2003) found no relationship between education and the likelihood of giving. The lack of a relationship between education and giving in this analysis may have been due to the inclusion of a squared education variable and a number of other variables. Tiehen (2001) did find a substantial relationship between years of education and amounts donated, using data from a larger number of US 'Giving and Volunteering' surveys.

Using data from the 1995 Consumer Expenditure Survey in the US, Yen (2002) found a positive relationship of education with secular giving, but no relationship with religious giving. This study used a sophisticated econometric model to take the simultaneity between religious and secular giving into account. The result suggests that the positive relationship between education and religious giving in other studies is due to omitted variables.

Using data from a later edition of the same dataset but collapsing religious and secular giving, Brooks (2002) found no relationship of education with the amount donated to charities in a tobit regression of data, controlling for income, wealth, age and welfare income.

Field of education

Many studies report differences in donations between graduates in specific fields of education. Yet the picture emerging from these studies is far from clear. In the Netherlands, Bekkers and De Graaf (2006) found that graduates in social work and the social sciences, in agriculture and in security donated higher amounts, controlling for a large number of variables. The finding on the higher amount donated by graduates in the social sciences is in line with results of a study of alumni giving to a small liberal arts college in the US, reported by Wunnava and Lauze (2001), who found that majors in social sciences gave more. However, a study of alumni donations to two medium-sized universities in the UK found that law graduates donated the highest amounts, and social science graduates gave the lowest amounts, along with graduates

in education, medicine and commerce (Belfield and Beney, 2000). These differences are not easily explained as the study included controls for a variety of potentially confounding variables such as gender, marital status, income and solicitation.

Experiments conducted by economists among university students and professors in economics have typically found economists to give less than students and professors in other social sciences (Frank et al, 1993, 1996; Frank and Schulze, 2000; Smith and Ehrenberg, 2003; Frey and Meier, 2004a, 2005; Eckel et al, 2005). A study of giving to the social funds of the University of Zurich, Switzerland (Frey and Meier, 2004a, 2004b) found not only lower giving among current students in economics, but also among students in computer science, theology, law and natural science (compared with students in arts and medicine) It seems possible that students who selected a field of study that includes courses on price theory, bargaining and rational choice and professors who teach such courses might be less likely to donate money to a charity without getting some kind of reward in exchange. However, economics graduates seem to be different from economics students and professors. Bekkers and De Graaf (2006) found that economics graduates did not differ from other graduates in their donations to charities in the Netherlands. Another study on alumni giving to a major university in the Netherlands also found no differences between economics graduates and graduates in other fields (Bekkers, 2010a). Blumenfeld and Sartain (1974) further found that business school students and economics graduates were more likely to donate to their alma mater than other students. This result may reflect a better income position among economics and business school graduates as the study did not include a measure of income. Another study lacking an income measure also found higher giving by business and economics alumni (Okunade et al, 1994). In a study of alumni at Vanderbilt University, Marr et al (2005) found that alumni with economics, mathematics and social science majors were more likely to contribute to their alma mater, while performing arts and science majors had a lower likelihood to make donations, controlling for income. In a study among young graduates of a selective group of private universities in the US, Monks (2003) found that graduates with an MBA or law degree gave more to their alma mater than those without an advanced degree, controlling for income. Monks also found that graduates with a major in fine arts or nursing gave significantly less, while history majors gave significantly more than humanities majors. Graduates with other majors (including business and management and social sciences) did not differ from humanities majors.

In sum, the findings on differences between alumni in different fields of study are inconsistent and vary from study to study. Given the few nationally representative studies, it may be that differences in the effects of field of study on giving vary from university to university within and between countries.

Cognitive ability

People with higher scores on a vocabulary test donate more (Bekkers, 2006a, 2006b; Bekkers and De Graaf, 2006; Wiepking and Maas, 2009a; James, 2011). A study of hypothetical measures of altruism also revealed a positive relationship between altruism and intelligence measured with an IQ test (Millet and Dewitte, 2007). A study of

alumni contributions found that contributions increase with Grade Point Average (Marr et al, 2005).

The relationship between cognitive ability and philanthropy is puzzling and cannot easily be explained. Obviously cognitive ability and the level of education are highly correlated, but establishing the direction of causality is tricky. In spite of this problem, the available evidence clearly shows that the relationship between cognitive ability and giving persists when the level of education is kept constant. This suggests that the positive relationship between cognitive ability and giving is not the result of the higher level of completed education found among those with more cognitive ability. A speculative explanation is that those with more verbal ability have a higher ability to cope with complex information or are more aware of social needs (Bekkers, 2006b). A finding supporting this interpretation is that students who view the world in more abstract terms were found to donate more often to homeless people (Levy et al, 2002). However, this study was conducted only among students in higher education. Research among a broader sample is needed to test whether greater awareness of need explains the relationship between cognitive ability and giving.

Response bias

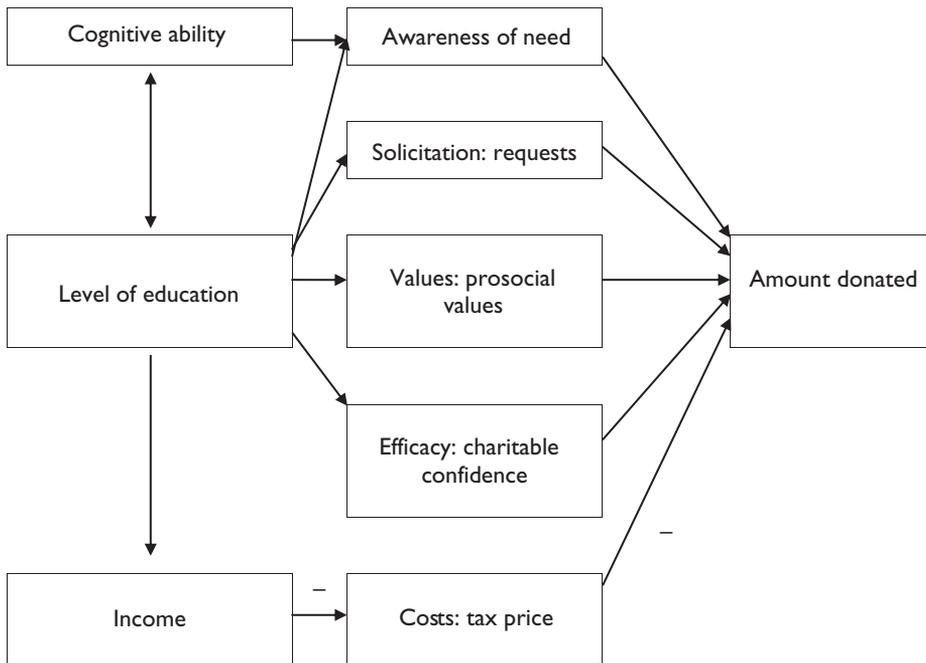

To some extent, the relationship found between education and giving may be an artefact resulting from imperfect methodologies. One study comparing self-reported donations in two surveys showed that lower-educated people were more likely to misunderstand survey questionnaires and were more likely to forget about donations they had made in the past year (Bekkers and Wiepking, 2006). Another study, comparing self-reported donations to a major charity in the Netherlands with donations as registered by the organisation, found that higher-educated persons were more likely to overestimate donations in the previous year (Bekkers and Wiepking, 2010a). These results suggest that the strength of the positive relationship between the level of education and giving is overestimated when using self-reported survey data. Nonetheless, registered donations increased significantly with the level of education. This indicates that the relationship between the level of education and giving is not merely a methodological artefact or a response bias.

Mechanisms

Why education matters for giving is far from settled. While some studies have directly investigated the mechanisms that may be involved, few studies have examined several mechanisms at once. This is unfortunate because it is likely that multiple mechanisms explain the relationship between education and giving. Such mechanisms could include awareness of need, solicitation, costs and values. Figure 2 displays the likely relationships.

Awareness of need and the level of exposure to information about charitable causes to support are likely to be higher among those with higher cognitive ability and among the higher educated (Bekkers, 2006b). The number of requests for donations is also likely to be higher among the higher educated. Brown (2005) and Brown and Ferris

Figure 2: Mechanisms explaining the relationships between charitable giving and level of education

Note: All displayed relationships are positive unless noted otherwise

(2007) found that higher education increased donations because it drew people into memberships. A likely explanation of this finding is that memberships entail higher levels of solicitations. In the Netherlands, Bekkers (2005a, 2005b) established that the strength of the association between the level of education and the amount donated to charitable causes diminished when the number of solicitations was controlled statistically, but that the association remained sizeable. At least in the Netherlands, exposure to a larger number of solicitations is not a complete explanation of the higher amounts donated by the more highly educated.

In their study of US philanthropy, Brown and Ferris (2007) found that education and giving were related not only through memberships but also through generalised social trust. People who were more trusting of others were likely to have more confidence in charitable organisations, suggesting a role for the mechanism of efficacy. Analyses of the Giving in the Netherlands Panel Survey (Schuyt et al, 2004; Bekkers, 2006a) show that higher education is related to giving to a variety of specific causes through generalised social trust and enhanced confidence in charitable organisations.

In addition, the analyses of the Dutch data also suggest that higher verbal intelligence and income are variables that explain the higher amounts donated by the higher educated. Wiepking and Maas (2009b) even found that the effect of education on the total amount donated to charitable causes was completely mediated by higher verbal intelligence and higher income. While it is difficult to interpret the relationship

between giving and verbal intelligence, the relationship with income seems less obscure. In countries with a progressive tax regime, citizens in higher income brackets face lower costs for giving when their donations are tax deductible. In Part Two of this paper, which will appear in a forthcoming issue of *Voluntary Sector Review*, we will discuss further the evidence on the relationship between income and giving.

A final explanation of the relationship between the level of education and giving is through the values mechanism. A study in the Netherlands showed that the higher educated more strongly endorsed social responsibility values than the lower educated (Schuyt et al, 2004). The same study showed that controlling for social responsibility diminished the relationship between the level of education and the amount donated.

Age

The typical finding about the relationship of age with philanthropy in the literature is that it is positive (Feldstein and Taylor, 1976; Boskin and Feldstein, 1977; Clotfelter, 1980; Yavas et al, 1981; Reece and Zieschang, 1985; Feenberg, 1987; Kingma, 1989; Midlarsky and Hannah, 1989; Auten and Rudney, 1990; Bristol, 1990; Jones and Posnett, 1991a, 1991b; Lankford and Wyckoff, 1991; Auten et al, 1992; Brown and Lankford, 1992; Choe and Jeong, 1993; Greenwood, 1993; Hoge and Yang, 1994; McClelland and Kokoski, 1994; Okunade et al, 1994; Pharoah and Tanner, 1997; Regnerus et al, 1998; Banks and Tanner, 1999; Chua and Wong, 1999; Duquette, 1999; Todd and Lawson, 1999; Belfield and Beney, 2000; Long, 2000; Eaton, 2001; Farmer and Fedor, 2001; Lunn et al, 2001; Tiehen, 2001; Wunnava and Lauze, 2001; Brooks, 2002; Eschholz and Van Slyke, 2002; Reed and Selbee, 2002; Bekkers, 2003, 2006b; Bryant et al, 2003; Eckel and Grossman, 2003; Apinunmahakul and Devlin, 2004; Frey and Meier, 2004a, 2005; List, 2004; Chang, 2005; Eckel et al, 2005; Lyons and Passey, 2005; Rooney et al, 2005; Yamauchi and Yokoyama, 2005; Bekkers and Wiepking, 2006; Carman, 2006; Carroll et al, 2006; Houston, 2006; Lyons and Nivison-Smith, 2006; Matsunaga, 2006; Mesch et al, 2006; Weerts and Ronca, 2007; Alpizar et al, 2008; Bekkers and Schuyt, 2008).

The majority of studies that have tested for quadratic trends found that the age relationship decreased at higher ages (Clotfelter, 1980; Glenday et al, 1986; Auten et al, 1992; Brown and Lankford, 1992; Okunade et al, 1994; Belfield and Beney, 2000; Putnam, 2000; Zech, 2000; Lunn et al, 2001; Tiehen, 2001; Wunnava and Lauze, 2001; Bryant et al, 2003; Simmons and Emanuele, 2004; Chang, 2005; Lyons and Nivison-Smith, 2006).

While the exact age at which the age gradient becomes weaker varied from study to study, it tended to be after the age of 65. Auten and Joulfaian (1996) found that donations were higher among those aged 40–84 than among those younger or older. Hodgkinson and Weitzman (1996) and Andreoni (2001) found a positive relationship until age 75, after which a decrease was observed. Midlarsky and Hannah (1989), Daneshvary and Luksetich (1997), Belfield and Beney (2000), Wu et al (2004) and Landry et al (2006) found a decrease in giving after the age of 65. In a study with a large proportion of respondents over the age of 65, Schlegelmilch et al (1997) found a negative relationship between age and the likelihood of giving to charity. Brown and

Lankford (1992) found an increase of donations with age that levelled off after the age of 45. In contrast to these results, Randolph (1995) found that giving increased with age, at an increasing rate for those over the age of 40; a discrepancy that may be explained by the fact that Randolph did not include variables for the number of children and marital status other than marriage.

An early study by Feldstein and Clotfelter (1976) found no significant age differences in the amount donated. A later study had the same result, controlling for a large number of background and context characteristics (Schiff, 1990). Rooney et al (2001) did not find a significant relationship between age and charitable giving in analyses including income, tax itemisation status, minority status, sharing a household, education and gender. Feldman (2007) found no relationship of age with the likelihood of making donations in a study including a wide variety of control variables. Taken together, the results of these studies suggest that the relationship of age with giving is due in part to other variables correlated with age, such as religion, marital status and income.

Specific populations

Three studies that focused on specific populations found no age differences in giving. Age was not related to giving in a study of business school alumni giving in the US (Okunade and Berl, 1997) and in a study on giving in Indonesia (Okten and Osili, 2004). Similarly, Park and Park (2004) found no relationship between age and donations in Korea.

Interaction of age, gender and income

There seem to be gender differences in the relationship between age and giving. Duncan (1999) found a significant age relationship for wives although not for husbands. A similar gender difference was found in a study of religious contributions (Sullivan, 1985). Daneshvary and Luksetich (1997) found that age differences varied by income: at higher income levels, giving did not decline after the age of 65.

Specific types of giving

Religious giving seems to be more strongly related to age than secular giving is. Reece (1979) and Hrung (2004) found a significantly positive relationship between age and religious giving, but not with other giving. Yen (2002) found a positive relationship of age with giving to religion and 'charity', but not to 'other organisations'. In contrast to these findings, however, Brown and Ferris (2007) found a positive but declining relationship between age and the amount donated to secular causes, but only a positive relationship of age with giving to religious organisations at higher ages. Several studies of giving to specific types of secular causes found no age differences. This was the case for donations to human services (Marx, 2000), to panhandlers (Lee and Farrell, 2003) and to professional societies, recreational organisations and women's organisations (Knoke, 1990).

Wiepking (2006) found a positive relationship between age and donations to organisations that used appeal letters as a fundraising method in the Netherlands. In contrast, she also found that older people had a lower probability of donating to organisations that solicited donations by means of door-to-door collections. This is likely due to the inclination of older people not to answer the door during evenings (Wiepking, 2010).

Mechanisms

Why age is related to giving is unclear. Generally speaking, age differences can be due to life-cycle effects or cohort effects, that is, the stage of one's life or the generation to which one belongs (Alwin and Krosnick, 1991). In a single set of cross-sectional data, individuals with a higher age are born earlier and have lived longer. To disentangle life-cycle and cohort effects, a set of repeated cross-sectional surveys is required. Using such data, Wilhelm et al (2007) showed that age differences in giving were a function of both life-cycle effects and cohort differences.

Both life-cycle effects and cohort differences often boil down to arguments about omitted variables. Age differences could simply be due to differences in variables correlated with age, such as income and religious involvement. An obvious life-cycle explanation is that disposable income increases with age. However, the age relationship persists in many studies controlling for income. Another factor to consider is religion. Olson and Caddell (1994) and Bekkers and Schuyt (2008) found that the relationship with age diminished once church attendance was controlled. This finding suggests that older people give more because their level of religious involvement is higher. Yet the age relationship does not disappear completely when religious involvement is controlled, indicating that other mechanisms play a role as well.

The mechanism of altruism may explain the life-cycle effect of age in a different way. The result found in Auten and Joulfaian's (1996) study – that age differences declined when children's income was controlled – suggests that older people donate more when they are less concerned about their children's financial future. The shift from benefiting children to donating to charitable causes may indicate a generic desire to contribute to the wellbeing of others. Older people may be more responsive to the needs of others because their children's needs are met. The ageing of the population in times of increasing wealth and decreasing numbers of children per family may constitute a promising fundraising future for charitable organisations.

Another life-cycle explanation for the increase of giving with age is that in old age people are closer to the end of their lives. An experiment showed that reminding students about death led them to give more to a charity (Jonas et al, 2002). Mortality salience may increase the psychological benefits of giving. However, no research to date has explored this mechanism.

Cohort explanations for the age differences in giving have received less attention in the literature. Wilhelm et al (2007) showed that generational differences in religious involvement explained the lower than expected giving by baby boomers. This finding is all the more interesting because younger generations on average have higher levels of education. Given the positive relationship between the level of education and charitable giving, one would expect younger cohorts to give more than older cohorts,

rather than less. Because Wilhelm et al's (2007) analysis did not include an education variable, it is difficult to evaluate the effect of changes in average education. Strictly speaking we can only conclude that the increase in education has not compensated for the negative effect of lower religious involvement among younger cohorts.

Socialisation

While relatively few studies have looked at the influence of parental background on giving, it is likely that parental characteristics affect children's giving behaviour.

Parental education, income and family stability

Material circumstances in the family of origin affect many child outcomes, including religiosity, education, income, health and longevity. As these variables are all predictive of giving, it is likely that positive material conditions in childhood are correlated with higher giving in adulthood. Indeed, the level of parental education was found to be positively related to the amount donated in the Netherlands (Bekkers, 2005a). Conversely, a US study found that low income and family instability in childhood was related to lower giving in adulthood (Bandy and Wilhelm, 2007). Two studies on alumni contributions showed that current parental income (Marr et al, 2005) and current parental church attendance (Lunn et al, 2001) increased giving.

Religious socialisation

Simmons and Emanuele (2004) found that people brought up in a religious household gave higher amounts. While this result is difficult to interpret as a socialisation effect because the analysis did not contain a measure of current religiosity, a study including such a measure and a variety of other controls did provide evidence for a religious socialisation effect (Bekkers, 2005a).

The effect of religious socialisation does not extend to all types of giving. Regnerus et al (1998) found that the importance of religion in one's family of youth was not positively related to donating to organisations that help the poor and the needy once current church attendance and importance of religious faith were controlled. Hoge and Yang (1994) found that having attended religious Sunday School was associated with higher religious giving among Catholics, but not among Protestants. In more extensive regression models, the relationship was found to disappear once salience of religion, private religious practices and current church attendance were included. This result suggests that religious socialisation influences current religious giving through current religiosity. In their study among Presbyterians, Lunn et al (2001) found that the frequency of parents' church attendance when the respondent was a teenager was positively related to religious giving in a regression analysis including personal and spousal religious affiliation, personal church attendance and theological beliefs. Parental church attendance was not related to non-religious giving. Using data from the 1974 National Survey of Philanthropy, a representative sample of US citizens, Schiff (1990) comes to a similar conclusion.

In the study by Lunn et al, being raised in the Presbyterian church was associated with less religious giving but there was no relationship with secular giving. This result may be explained as a selection effect. Among those who were not raised in the church, some were converted at a later age. It is likely that these individuals are prepared to donate substantially to the church; otherwise they would have chosen not to become a member.

Parental modelling

Giving is a form of prosocial behaviour that is often encouraged by parents: many people recollect that their parents taught them the value of helping others by volunteering themselves (Independent Sector, 2000). A study in the US including a wide variety of controls (Wilhelm et al, 2008) found that concurrent giving by parents and children were significantly correlated. Because parental giving behaviour in the past may be difficult for people to remember, most studies have sought to test parental modelling effects through questions on parental volunteering. While parental volunteering was found to be related to the likelihood of donating in one US study (Feldman, 2007), it was not found to be related in another (Bryant et al, 2003). In the Netherlands, volunteering by parents in respondents' childhood was found to be associated with current giving, even when a wide variety of controls were included (Bekkers, 2005a). Parental volunteering was not related to the proportion of income donated when other correlates of giving were included (Schervish and Havens, 1997).

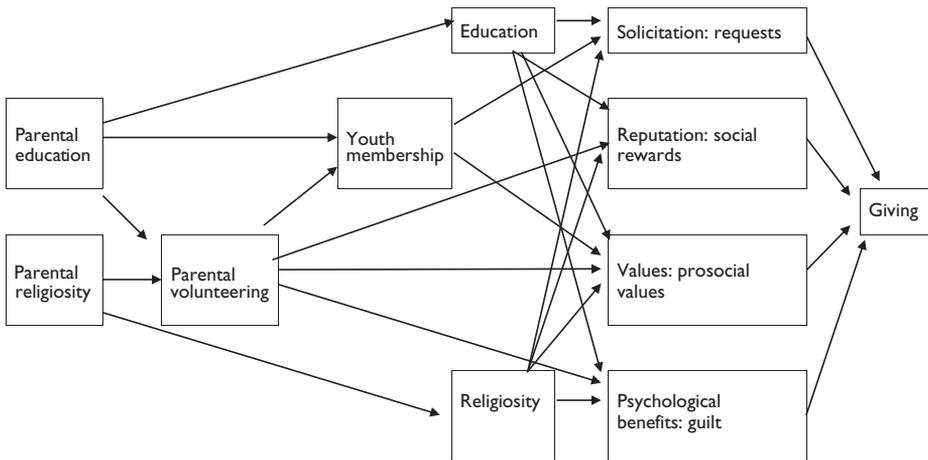

Youth participation

A simple analysis by the Independent Sector (2000) comparing mean values revealed that adults in the US who reported activity in voluntary associations when they were teenagers gave more as adults. Feldman (2007) found that this bivariate association held when numerous controls were included. Using data from the Giving in the Netherlands Panel Study among adults in the Netherlands, Bekkers (2005a) obtained a similar finding. The study also revealed that youth participation was one of the channels through which parental background affected giving by children. Children of higher-educated parents, children of parents who were more strongly involved in religion and children of parents who volunteered themselves when their children were young were giving higher amounts as adults because these children were more likely to be engaged in voluntary associations.

Mechanisms

The preceding discussion shows that socialisation characteristics such as a religious upbringing, parental education and material circumstances, parental volunteering and youth membership are interconnected and likely to be related. Figure 3 summarises these connections.

Figure 3: Mechanisms explaining the relationships between giving and socialisation characteristics

Note: All displayed relationships are positive

In addition, the figure shows the mechanisms that are likely to explain the relationship between youth membership, parental volunteering and giving. Youth participation strengthens the social bonds of children in a community, making them accessible for non-profit organisations. One study that explicitly measured this mechanism shows that youth participation is associated with current giving through solicitations for contributions (Bekkers, 2005a). The same study showed that respondents who reported memberships of youth organisations more strongly endorsed prosocial values such as social responsibility and altruistic values. Controlling for the presence of these values reduced the magnitude of the relationship between youth memberships and current giving. Solicitation and values are thus likely to be important mechanisms establishing a link between youth participation and philanthropy.

Encouragement to engage in philanthropy by parents – either by deeds or by preaching – yields social pressure on children to engage. As a result, children may engage in philanthropy because of reputational concerns. A second mechanism through which the parental example affects giving by their children is through values. Parental encouragement may result in the internalisation of prosocial values (Eisenberg, 2000), leading to philanthropy. A third mechanism is solicitation: children of parents who volunteered in the past receive higher numbers of solicitations for charitable contributions (Bekkers, 2005a). A fourth mechanism potentially linking parental volunteering to giving is the psychological benefit associated with giving. Children of parents who volunteered are more likely to view giving to others as an important goal in their lives. For them, living up to that goal is likely to produce a sense of satisfaction. To date, however, no study has tested this possibility.

Discussion

The interest in research on 'who gives' is often motivated by the goal of attracting or retaining donors. Fundraisers can use knowledge on 'who gives' to create donor profiles in order to target campaigns at those who are most likely to give and/or who will give higher amounts. Fundraisers and policy makers can also use this type of knowledge to understand trends and predict future changes in the size and nature of philanthropy. When using knowledge on 'who gives' for these purposes, two warnings should be put in place. First, the majority of studies analyse donations without controlling for the number of solicitations received. Knowing that religious people give more than non-religious people does not necessarily imply that religious people are more likely to respond positively to an additional solicitation for donations. In fact, several studies show that when solicitation is kept constant, religious people are not more likely to donate to secular organisations than non-religious people (Eckel and Grossman, 2004; Bekkers, 2007, 2010b). Increasing the number of solicitations among religious people may therefore be cost-inefficient. Moreover, growing donor irritation with the number of fundraising approaches may lower donations in the future.

Also, in most studies, cross-sectional data are used to establish the predictors of charitable giving. Strictly speaking, no conclusions can be drawn from cross-sectional data about the causality of the relationship between predictors, such as religious beliefs and the level of education, and charitable giving. For causal inferences either experiments or longitudinal data and appropriate statistical models are needed. As far as we know, there are only two publicly available longitudinal datasets that include measures of charitable giving: the US Center on Philanthropy Panel Study (COPPS), a supplement to the Panel Study of Income Dynamics (PSID) (PSID-COPPS, 02-10), and the Dutch Giving in the Netherlands Panel Study (GINPS, 2001-07). The two datasets have different strengths. COPPS has high-quality wealth and income data, has a high response rate and can be linked to other PSID modules such as the Child Development Supplement (Wilhelm, 2006). GINPS, in contrast, includes measures for several of the mechanisms that drive philanthropy, such as solicitation, social values and efficacy (Bekkers and Schuyt, 2008). We think that considerable progress in the study of philanthropy can be made by analysing these two panel datasets and by creating more panel data for other countries. We applaud the initiatives of researchers in Austria and South Korea who have recently taken such steps, and we hope that many other researchers will follow.

Limitations

As the above discussions about mechanisms show, most of the knowledge on who gives what is of limited value to scholars who want to test causal theories about determinants of individual and household giving or to fundraisers who wonder how they should design successful fundraising campaigns. Few studies have included measures of the mechanisms that may explain relationships between predictors and charitable giving. Without these measures, we are often left with several possible

explanations that are not mutually exclusive. As a result, we have a lot of descriptive knowledge about who gives what but we have very little knowledge about why some people give more than others. We urge our colleagues to advance the state of research on philanthropy by testing the mechanisms explaining relationships of sociodemographic characteristics with giving. Including measures of mechanisms in new data collection exercises will enable future researchers to better understand why some people give more than others.

Notes

¹ Corresponding author.

² We have omitted differences between religious denominations from this figure. For each denomination a separate variable would have to be included. This would make the figure very complex.

Acknowledgements

The groundwork for this paper was partly funded by the John Templeton Foundation and grant #451-04-110 of the Netherlands Organisation for Scientific Research (NWO) to Bekkers and grant #451-09-022 of the NWO to Wiepking.
